### ABSTRACT

The rotator cuff consists of several tendons and muscles that provide stability and force transmission in the shoulder joint. Whereas most rotator cuff tears are amenable to suture repair, the overall success rate of repair is low, and massive tears are prone to re-tear. Extracellular matrix (ECM) patches are used to augment suture repair, but they have limitations. Tissue-engineered approaches provide a promising solution for massive rotator cuff tears. Previous studies have shown that, compared to nonaligned scaffolds, aligned electrospun polymer scaffolds exhibit greater anisotropy and exert a greater tenogenic effect. Nevertheless, achieving rapid cell infiltration through the full thickness of the scaffold is challenging, and scaling to a translationally relevant size may be difficult. Our goal was to evaluate whether a novel method of alignment, combining a multilayered electrospinning technique with a hybrid of several electrospinning alignment techniques, would permit cell infiltration and collagen deposition through the thickness of poly( $\epsilon$ -caprolactone) scaffolds following seeding with human adipose-derived stem cells. Furthermore, we evaluated whether multilayered aligned scaffolds enhanced collagen alignment, tendon-related gene expression, and mechanical properties compared to multilayered nonaligned scaffolds. Both aligned and nonaligned multilayered scaffolds demonstrated cell infiltration and ECM deposition through the full thickness of the scaffold after only 28 days of culture. Aligned scaffolds displayed significantly increased expression of tenomodulin compared to nonaligned scaffolds and exhibited aligned collagen fibrils throughout the full thickness, the presence of which may account for the increased yield stress and Young's modulus of cell-seeded aligned scaffolds along the axis of fiber alignment.

### Statement of Significance

Rotator cuff tears are an important clinical problem in the shoulder, with over 300,000 surgical repairs performed annually. Re-tear rates may be high, and current methods used to augment surgical repair have limited evidence to support their clinical use due to inadequate initial mechanical properties and slow cellular infiltration. Tissue engineering approaches such as electrospinning have shown similar challenges in previous studies. In this study, a novel technique to align electrospun fibers while using a multilayered approach demonstrated increased mechanical properties and development of aligned collagen through the full thickness of the scaffolds compared to nonaligned multilayered scaffolds, and both types of scaffolds demonstrated rapid cell infiltration through the full thickness of the scaffold.

## 1. Introduction

The prevalence of rotator cuff tears increases with age to >50% in individuals over the age of 60 [1,2]. Currently, over 300,000

surgeries are performed annually in the United States to repair rotator cuff tears [3], and this number is likely to rise with the projected increase in elderly populations [4]. Re-tear rates are high, especially with increasing tear size [5,6], and massive rotator cuff tears may not be amenable to traditional suture repair [7]. In this regard, tissue engineering approaches to enhance or augment traditional suture rotator cuff repair could have significant clinical impact. Extracellular matrix (ECM) patches have been used to augment repair but generally have inadequate mechanical properties

[8], and slow cell infiltration prevents rapid integration of many commercially available ECM patches [9,10].

Therefore, there is a need for tissue-engineered approaches that both stimulate rapid tendon healing and provide adequate mechanical augmentation for the rotator cuff [11]. Electrospun scaffolds have shown significant potential in this regard [12–15], but do not yet provide adequate mechanical properties. A further challenge has been achieving cell infiltration through the full thickness of the scaffold [16,17]. Various methods to improve porosity of the electrospun scaffold have been evaluated [16,18–22]. To address this need specifically for rotator cuff tendon tissue engineering, we have recently modified a multilayered electrospinning technique [22] to achieve rapid infiltration of human adipose-derived stem cell (hASC) and tenogenic ECM synthesis through the full thickness of randomly multilayered electrospun scaffolds [23]. However, several recent studies indicate that, compared with nonaligned or randomly oriented fibers, aligned nanofibers can enhance tenogenesis [12,24,25]. Furthermore, such fiber alignment creates mechanical anisotropy that more closely mimics tendon mechanical properties. Electrospun fiber alignment can be achieved through the use of a rotating disk [26–28], rotating mandrel [29–31], patterned electrodes [32,33], air-gap techniques [34,35], patterned insulators [36], or ceramic magnets [37–39]. However, as with nonaligned scaffolds, achieving cell infiltration can be problematic when using rotating mandrel techniques, unless sacrificial fibers are simultaneously co-spun [16,40]. Air-gap techniques are typically limited by short lengths of fiber alignment (~1 cm) [41] or by decreasing alignment with increasing duration of electrospinning [35]. Multilayered aligned scaffolds (produced by stacking aligned layers on top of each other) across short lengths of fiber alignment have previously been reported to control the hierarchical structure within the scaffold [36,42], and thus may be advantageous for the development of scaffolds for rotator cuff tendon tissue engineering [24,25]. The objectives of this study were to (1) to develop a novel multilayered electrospinning technique that allows for prescribed alignment of each layer in a clinically relevant patch size, and (2) to evaluate the ability of these aligned scaffolds to induce complete cellular infiltration, tenogenic ECM formation, and development of tensile mechanical properties by hASCs compared to nonaligned multilayered scaffolds.

## 2. Materials and methods

### 2.1. Aligned multilayered electrospun scaffolds

Poly( $\epsilon$ -caprolactone) (PCL) (Mn = 80,000) (Sigma–Aldrich, St. Louis, MO) was dissolved at 100 mg/mL in 7:3 dichloromethane:ethanol for 24 h before use. Individual alignment methods (ceramic magnets, air-gap, patterned insulators, parallel copper electrodes) amenable to formation of multilayered square or rectangular patch scaffolds were first screened for their ability to induce aligned fiber formation over air-gaps of 5–8 cm, a size relevant for future clinical use. Each method of alignment was screened systematically using a range of polymer flow rates, voltages, needle sizes, needle-ground distance, and spinning times to most closely match fibers obtained using nonaligned techniques (see Section 2.2). As has been previously reported [32–34,36–39], each individual method was able to induce fiber alignment over a short (1–3 cm) air-gap, but as the size of the air-gap was increased, alignment was lost or was evident for progressively shorter periods of time before deposition of fibers occurred elsewhere (Fig. S1). However, when individual alignment methods were combined to include ceramic magnets and parallel copper electrodes outside of a rectangular rubber-coated reservoir

containing distilled water (volume dependent on ambient temperature and humidity), robust aligned layers were obtained for up to 5 min of electrospinning across an air-gap of 10 cm. Therefore, the final electrospinning apparatus used (Fig. 1) was a rectangular, rubber-coated reservoir (10 cm wide  $\times$  15 cm long) containing distilled water, with grounded 6-cm wide parallel copper electrodes immediately outside the reservoir centered at the midpoint of the reservoir length and immediately surrounded by ceramic magnets (2.5 cm  $\times$  7 cm  $\times$  14.5 cm) oriented to attract each other. The following electrospinning parameters were used: 21 G needle fitted with a round wire mesh focusing cage (3 cm diameter, needle tip protruding 4 mm from bottom of cage), 5 mL/h, 16 kV, and a 13.5 cm needle-to-ground distance. Aligned layers were collected sequentially from the surface of the saline bath every 3 min onto a 5 cm  $\times$  7.5 cm glass slide, for a total of 140 layers (approximately 1 mm thick).

### 2.2. Nonaligned multilayered scaffolds

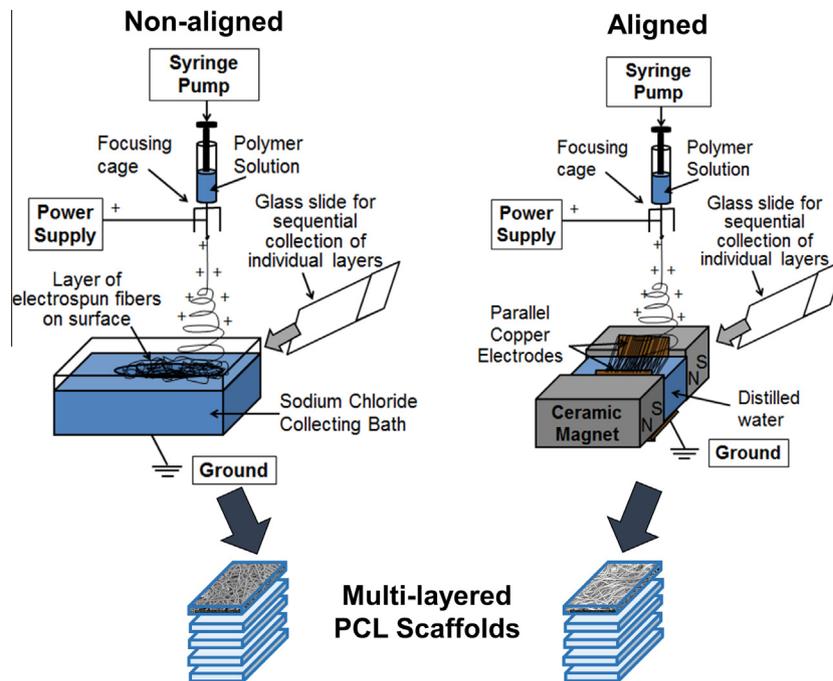

Nonaligned multilayered scaffolds were prepared by electrospinning into a grounded saline bath (1.25 g/L NaCl in distilled water) using the apparatus previously described (Fig. 1) [23]. PCL was electrospun using the following parameters: 25 G needle fitted with a round wire mesh focusing cage (3 cm diameter, needle tip protruding 4 mm from the bottom of the cage), 2.5 mL/h, 17 kV, and a 17 cm needle-to-ground distance. Nonaligned layers were collected sequentially from the surface of the saline bath every 2 min using a 5 cm  $\times$  7.5 cm glass slide, for a total of 70 layers (approximately 1 mm thick). Parameters were selected to obtain similar scaffold thickness and fiber diameters between aligned and nonaligned scaffolds (Section 3). For all scaffolds produced, relative humidity was 20–40%, and ambient temperature ranged from 18 °C to 25 °C. Each scaffold was allowed to dry at room temperature and then stored at room temperature protected from light until use.

### 2.3. Fiber diameter analysis

Three 0.5 cm  $\times$  1 cm strips were cut from each scaffold (center and two orthogonal edges), sterilized (see Section 2.4), critical point dried in CO<sub>2</sub>, and then sputter coated with gold. Each sample was viewed with a Philips 501 scanning electron microscope. Three representative images were taken of each sample, and the diameter of 100–150 fibers for each type of scaffold was measured in ImageJ (NIH, USA).

### 2.4. Cell seeding and culture

Scaffolds were cut into individual 0.5 cm  $\times$  1 cm strips with long axis parallel to the expected direction of fiber alignment and sutured to a Teflon ring to maintain shape and suspension in media. Scaffolds to be used for mechanical testing were cut into dog-bone shapes in directions parallel and perpendicular to the direction of expected alignment, and similarly for nonaligned scaffolds. Each scaffold was rehydrated and sterilized in a graded series of ethanol baths to improve seeding before a final 30-min rinse in phosphate-buffered saline (PBS) at pH 7.4. Both sides of each scaffold were sterilized under ultraviolet light for 10 min and pre-wetted with PBS before cell seeding. We isolated hASCs by collagenase digestion of lipoaspirate surgical waste from five de-identified female donors (age 36–59, body mass index 19.6–33.1) with approval of the Duke University Institutional Review Board and used the cells at passage 4 [23,43]. Cells were seeded at a density of  $1 \times 10^6$  hASCs/cm<sup>2</sup> for quantitative real-time reverse transcription polymerase chain reaction (qRT-PCR) and 0 or  $0.5 \times 10^6$  hASCs/cm<sup>2</sup> for all other assays. Half of the cells were

**Fig. 1.** Electrospinning apparatus for nonaligned and aligned electrospun scaffolds. Nonaligned layers are collected sequentially from the surface of a grounded saline collecting bath to form multilayered nonaligned scaffolds. Similarly, aligned layers are collected sequentially from between the alignment apparatus to form multi-layered aligned scaffolds.

seeded onto one side of the scaffold by direct pipetting and allowed to attach for 15 min, before the scaffolds were turned over and the procedure repeated. No gross differences in wettability or in cell seeding were noted between aligned and nonaligned scaffolds. Scaffolds were then maintained in 6-well plates coated with 2% agarose without growth factors at 37 °C and 5% CO<sub>2</sub> in Advanced DMEM (Life Technologies) supplemented with 10% fetal bovine serum (Zen-Bio), 1% penicillin–streptomycin–fungizone (Life Technologies), 4 mM L-glutamine (Life Technologies), and 15 mM l-ascorbic acid-2-phosphate (Sigma–Aldrich), which was changed every other day for the designated culture periods.

### 2.5. Biochemical assays

On days 0, 7, 14, and 28, unseeded and hASC-seeded nonaligned and aligned scaffolds ( $n = 5$  per group) were harvested and lyophilized to obtain dry weight. Samples were pulverized and digested for 1 week in papain (125 µg/mL) at 60 °C. The dsDNA content was quantified using the Picogreen Assay (Life Technologies). The sulfated glycosaminoglycan (s-GAG) content was quantified spectrophotometrically using the 1,9-dimethylmethylene blue dye (pH 3.0) [44]. The hydroxyproline assay was used to determine the total collagen content using a conversion factor of 1:7.46 to convert hydroxyproline to collagen [45]. All results were normalized to dry weight (mean ± SD).

### 2.6. RNA isolation and real-time qRT-PCR

RNA was extracted from hASC-seeded aligned and nonaligned scaffolds ( $n = 5$  per group) pulverized after harvest at 4, 7, and 14 days of cell culture, and from a pellet of cells of the same passage not seeded onto scaffolds, using the QiaShredder column (Qiagen) followed by the RNeasy Mini kit (Qiagen). Equal amounts of RNA were reverse transcribed using the Superscript VILO cDNA Synthesis Kit (Life Technologies). Real-time qRT-PCR was performed on a StepOnePlus (Applied Biosystems) using Express

qPCR SuperMix (Invitrogen) as described previously for glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*, endogenous control, assay ID Hs02758991\_g1) and six tendon-related genes: type I collagen (*COL1A1*), type III collagen (*COL3A1*), decorin (*DCN*), biglycan (*BGN*), tenomodulin (*TNMD*), and tenascin C (*TNC*) [23]. Data from each gene of interest for each sample were corrected for efficiency and normalized to expression of *GAPDH*. These data were then expressed as fold-change relative to the level of gene expression in 1 million P4 hASCs before cell seeding from each donor at day 0 [46].

### 2.7. Histology

Unseeded and hASC-seeded aligned and unaligned scaffolds ( $n = 5$ ) were harvested after 28 days of culture, embedded in optimal cutting temperature gel (Sakura), and frozen at -80 °C. We mounted 10-µm sections on slides and evaluated them under a Zeiss LSM 510 Confocal Microscope (Carl Zeiss) after immunofluorescence labeling of human type I and III collagen, as described previously [43].

### 2.8. Analysis of scaffold and matrix alignment

Evaluation of scaffold and ECM alignment were performed in two ways: First, 10 µm sections were digested with hyaluronidase after 0 and 28 days of culture ( $n = 5$  per group) and stained with 0.1% Picrosirius Red solution for analysis of aligned fibrillar collagen relative to the vertical gradient through the thickness of the scaffold using polarized light microscopy [47]. Second, aligned and unaligned scaffolds were harvested after 0, 7, and 28 days of culture ( $n = 5$  per group), fixed in 2.5% glutaraldehyde, incubated in osmium tetroxide, washed in PBS, dehydrated in a graded series of ethanol washes, and incubated in tetramethylsilane. After desiccation, samples were sputter coated and imaged by scanning electron microscope as described above. Six images were taken of each sample, then fast Fourier transform (FFT) was performed using a

custom MATLAB (MathWorks, Natick, MA) code [36], based on a modification of a previously described method [30]. FFTs from each image of the same scaffold type and time point were averaged and normalized to show the actual angle of alignment relative to the expected angle of alignment. The fiber alignment index was calculated from the average magnitude of the FFT profile for 15° on each side of the expected orientation [36].

### 2.9. Mechanical testing

After harvest at day 0 or 28, hASC-seeded dog-bone samples oriented parallel and perpendicular to the expected axis of alignment ( $n = 6$  per group) were wrapped in gauze soaked in PBS and stored at  $-80^{\circ}\text{C}$  until analysis. Samples were marked at 5-mm increments from the center of the dog bone to allow regional strain analysis, and initial scaffold thickness was measured using a digital camera (Allied Vision Technologies, Inc.) and digital calipers in ImageJ. Samples were tested as previously described [23], in tension at a strain rate of 1%/s with 0.5 g preload using an electromechanical testing system (Bose Enduratec Smart Test Series; Bose Corporation) with a 2.27 kg load cell (Sensotec Model 31; Honeywell International). Mid-substance strains were calculated from digital images acquired at 20 Hz and interpolated to load frame data using custom MATLAB code [23]. The Young's modulus of the linear region and stretch and stress at yield were calculated in Microsoft Excel.

### 2.10. Statistical analysis

Data are reported as median and interquartile range (25th–75th percentile) or mean  $\pm$  SD, tested for normality, transformed using Box-Cox transformation if necessary, and then evaluated for the effect of scaffold alignment, seeding, and time using factorial analysis of variance (ANOVA). The Newman-Keuls *post hoc* test was used to determine differences between treatments following ANOVA. Significance was reported at the 95% confidence level for all analyses ( $\alpha = 0.05$ ).

## 3. Results

Median fiber diameter of nonaligned scaffolds was  $1.57\ \mu\text{m}$  (1.20–2.53), and not significantly different ( $p = 0.61$ ) than those of aligned scaffolds,  $1.76\ \mu\text{m}$  (1.06–2.58). Scaffold thickness was reduced and different between scaffolds at the time of use relative to the thickness immediately after electrospinning (approximately 1 mm thick); aligned scaffolds were  $0.43 \pm 0.18$  mm thick and nonaligned were  $0.75 \pm 0.132$  mm thick ( $p < 0.001$ ). dsDNA, s-GAG, and collagen content of all scaffolds increased after cell seeding, and

there was no effect of fiber alignment (Fig. 2). On both types of scaffolds, gene expression was consistent with tenogenesis (Fig. 3). Between scaffold types, COL3A1 and TNMD expression was increased on aligned relative to nonaligned scaffolds (Fig. 3). Both aligned and nonaligned scaffolds demonstrated cell infiltration through the full thickness of the scaffold and type I and III collagen synthesis through the full thickness of the scaffold (Fig. 4). However, total collagen through the full thickness of the scaffolds, as assessed by Picosirius Red, was more abundant in aligned scaffolds. Under polarized light microscopy, only aligned scaffolds demonstrated substantial red birefringence through the full thickness of the scaffold (Fig. 4). This electrospinning alignment technique produced scaffolds with a fiber alignment index approximately 17 times greater than nonaligned scaffolds (Fig. 5), and was oriented in the expected direction of alignment. Fiber alignment index remained significantly greater in aligned scaffolds compared to nonaligned after 7 days of culture. However, by 28 days of culture, the fiber alignment index on the surface of aligned scaffolds was significantly less than nonaligned scaffolds at the same time point and less than aligned scaffolds at Day 0 and 7 (Fig. 5). Nonaligned scaffolds demonstrated an increase in fiber alignment index in the first 7 days of culture, and a small but significant decrease in fiber alignment index by 28 days of culture (Fig. 5). Aligned scaffolds showed significant anisotropy with respect to Young's modulus and yield stress, whereas unaligned scaffolds were isotropic (Fig. 6). After 28 days of culture, aligned scaffolds demonstrated significantly increased modulus and yield stress along the axis of fiber alignment, as compared to all other groups tested. Nonaligned scaffolds demonstrated an increase in Young's modulus over time, but no significant increase in yield stress or yield stretch with culture. Yield stretch (Fig. 6) did not demonstrate anisotropy but increased with cell seeding, and was greatest in aligned scaffolds.

## 4. Discussion

The novel multilayered alignment technique evaluated in this study demonstrated enhanced tensile mechanical properties and development of fibrillar collagen through the full thickness of a clinically relevant sized-scaffold after 28 days of culture compared to nonaligned multilayered scaffolds. These findings were accompanied by increases in TNMD and COL3A1 expression, and at early post-seeding time points, alignment of newly synthesized ECM on the surface of the scaffolds. Additionally, in both aligned and nonaligned scaffolds, we found complete cellular infiltration and type I and III collagen synthesis through the full thickness of the scaffolds, and gene expression consistent with tenogenesis and with our previous findings [23].

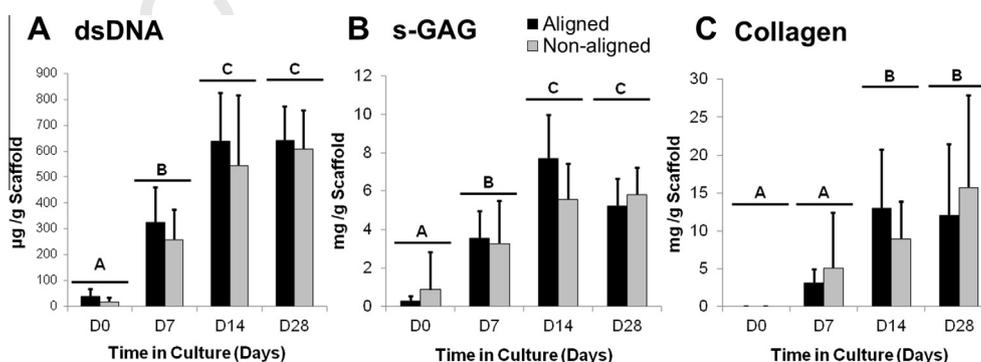

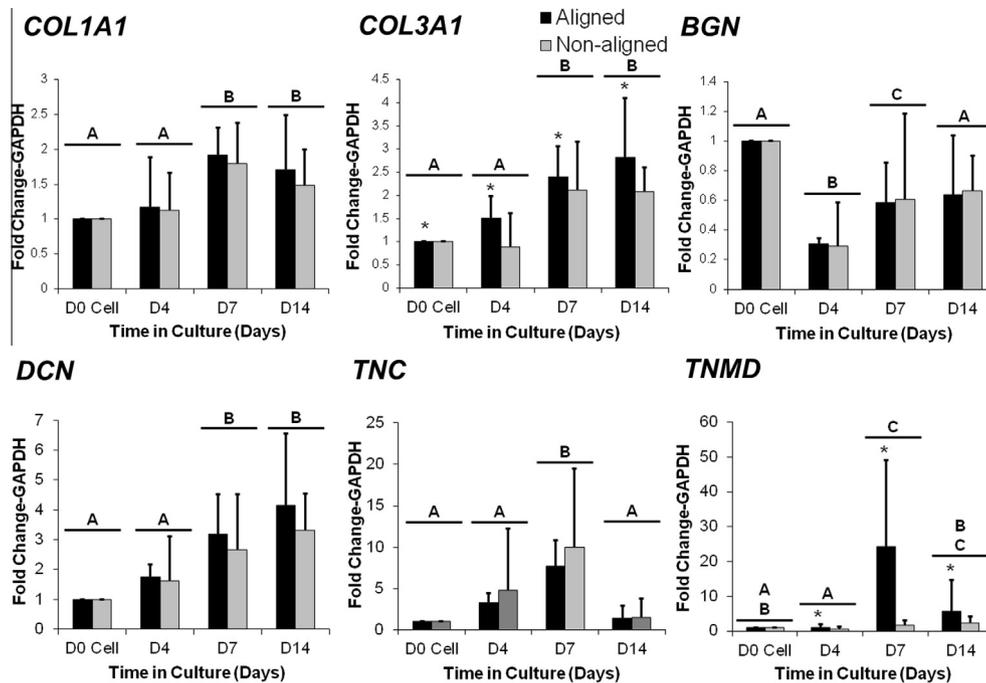

Fig. 2. Mean dsDNA (A), sulfated glycosaminoglycan (s-GAG) (B), and collagen (C) content of aligned and nonaligned multilayered electrospun poly( $\epsilon$ )caprolactone scaffolds 0, 7, 14, and 28 days after seeding with  $0.5 \times 10^6$  human adipose-derived stem cells/cm<sup>2</sup>. Whiskers indicate standard deviation;  $n = 5$  per group. Bars with different letters above are significantly different from each other,  $p \leq 0.05$ .

**Fig. 3.** Mean gene expression of type I collagen (*COL1A1*), type III collagen (*COL3A1*), biglycan (*BGN*), decorin (*DCN*), tenascin-C (*TNC*), and tenomodulin (*TNMD*) at 7, 14, and 28 days of culture normalized to day 0 and *GAPDH* expression. Whiskers indicate standard deviation;  $n = 5$  per group. Bars with different letters above are significantly different from each other,  $p \leq 0.05$ . \*Aligned greater than nonaligned,  $p \leq 0.05$ .

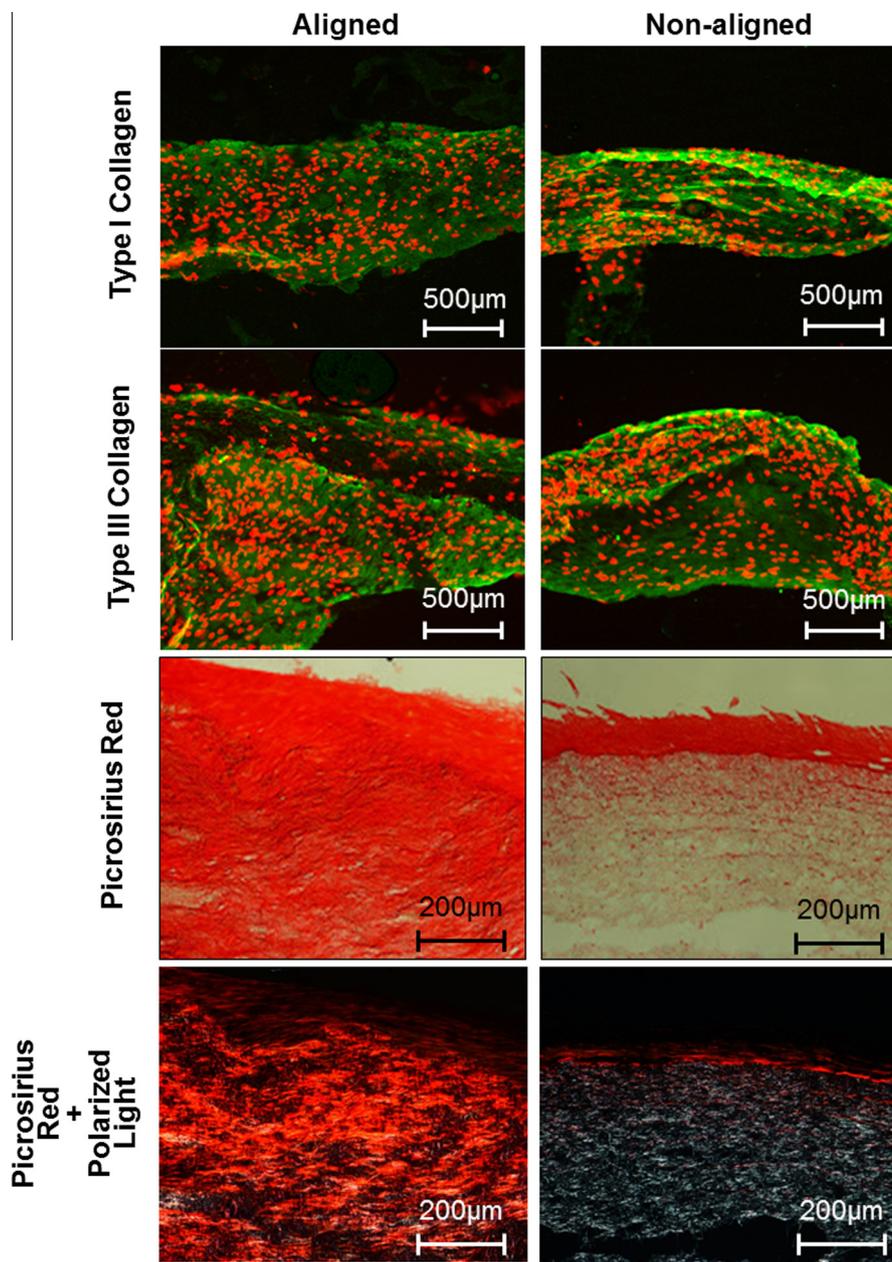

347 The most commonly reported technique for alignment of elec- 348  
349 trospun fibers is the use of a rotating ground electrode (i.e., man- 350  
351 drel or disk) [26–31,48]. While this technique readily allows for 352  
353 collection of a patch-like scaffold, achieving cell infiltration 354  
355 through scaffolds prepared in this manner requires the use of sac- 356  
357 rificial fibers [16], a combination of electrospinning and electro- 358  
359 spraying [16,40,49], or incorporation of biomimetic materials 360  
361 into the scaffold [50]. The alignment method used in this study 362  
363 was a hybrid of several other techniques previously reported, and 364  
365 it further improved cellular infiltration and control of fiber align- 366  
367 ment over clinically relevant scales as compared to these techni- 368  
369 ques used individually. Using the combination of alignment 370  
371 methods described, we achieved fiber alignment over an air-gap 372  
373 of 10 cm and successfully maintained fiber alignment with increas- 374  
375 ing fiber deposition for electrospinning periods of up to 10 min as 376  
377 has been reported with another similar technique [35].

363 As previously reported on nonaligned multilayered scaffolds 364  
365 [23], dsDNA, s-GAG, and collagen content increased over time 366  
367 in culture, but in this study there was no additional beneficial effect 368  
369 of scaffold alignment on the amount of matrix production. This 370  
371 phenomenon is consistent with previous studies, as matrix produc- 372  
373 tion in response to fiber alignment appears to be dependent pri- 374  
375 marily on cell type. For example, bone marrow derived 376  
377 mesenchymal stem cells (MSCs) but not rotator cuff tendon fibro- 378  
379 blasts demonstrate increased proliferation and collagen synthesis 380  
381 on aligned nanofibers compared to nonaligned nanofibers on scaf- 382  
383 folds of equivalent fiber diameter and cultured at similar density 384  
385 and in similar media [12,51]. Furthermore, anterior cruciate liga- 386  
387 ment fibroblasts increased proliferation and collagen synthesis 388  
389 on aligned scaffolds compared to nonaligned, although fiber dia- 390  
391 meter of nonaligned scaffolds was not described [52]. Others have 392  
393 shown that whereas bovine MSCs produce more ECM on aligned 394  
395 nanofibrous scaffolds than in pellet culture compared to donor- 396  
397 matched meniscal fibrochondrocytes, the opposite effect is 398  
399 observed in human MSCs [53,54].

382 The overall gene expression patterns observed in this study are 383  
384 consistent with tenogenesis and with our previous results in hASCs

384 [23,43]. In particular, the increase in *DCN* and initial decrease in 385  
386 *BGN* expression are consistent with tendon regeneration rather 387  
388 than repair [55,56]. *TNMD* is necessary for tenocyte prolifera- 389  
390 tion and collagen fibril maturation [57]; thus, the differential upregula- 391  
392 tion of *TNMD* on aligned scaffolds in this study is consistent with 393  
394 the finding of increased fibrillar collagen through the full thickness 395  
396 of aligned but not unaligned scaffolds, but investigation of other 397  
398 ECM components such as type VI collagen would be required to 399  
400 definitively link these findings [57]. Other studies evaluating gene 401  
402 expression on aligned and nonaligned scaffolds have not found dif- 403  
404 ferences in tendon gene expression between aligned and non- 405  
406 aligned nanofibers [12,51,58]. However, in this study, fiber 407  
408 diameter was more than double that reported in others [12,51], 409  
410 and micro- rather than nanofiber diameter has been found to pro- 411  
412 mote expression of tendon phenotypic markers by human fibro- 413  
414 blasts, notably *COL1A1*, *COL3A1*, and *TNMD* [59].

400 In this study, robust cell infiltration and type I and III collagen 401  
402 synthesis were observed through the full thickness of the scaffold 403  
404 after only 28 days in culture as we have seen previously for non- 405  
406 aligned scaffolds [23], irrespective of fiber alignment. This finding 407  
408 is in contrast to other *in vitro* studies, in which complete cell infil- 409  
410 tration required 70 days of culture in aligned scaffolds [53], unless 411  
412 sacrificial fibers were included within the scaffold to achieve com- 413  
414 plete cell infiltration within 21 days [16]. The rate of cellular infil- 415  
416 tration that occurred was not specifically evaluated in this study, 417  
418 but in the original description of the nonaligned multilayered tech- 419  
420 nique used here, Tzezana et al. [22] found almost complete infiltra- 421  
422 tion of myofibroblasts or embryonic stem cells by 14 days after 423  
424 seeding compared to single-layer scaffolds, and suggested that 425  
426 enhanced cellular migration in multilayered scaffolds may be fac- 427  
428 ilitated through enhanced interconnectivity between individual 429  
430 pores. In support of this, we have previously found infiltration of 431  
432 cells through only the outer third of nonaligned single-layer scaf- 433  
434 folds after 28 days of culture, in contrast to full-thickness infiltra- 435  
436 tion in nonaligned 60-layer scaffolds at the same time point [36]. 437  
438 Despite similar type I and III collagen synthesis identified by 439  
440 immunofluorescence microscopy between aligned and nonaligned 441  
442

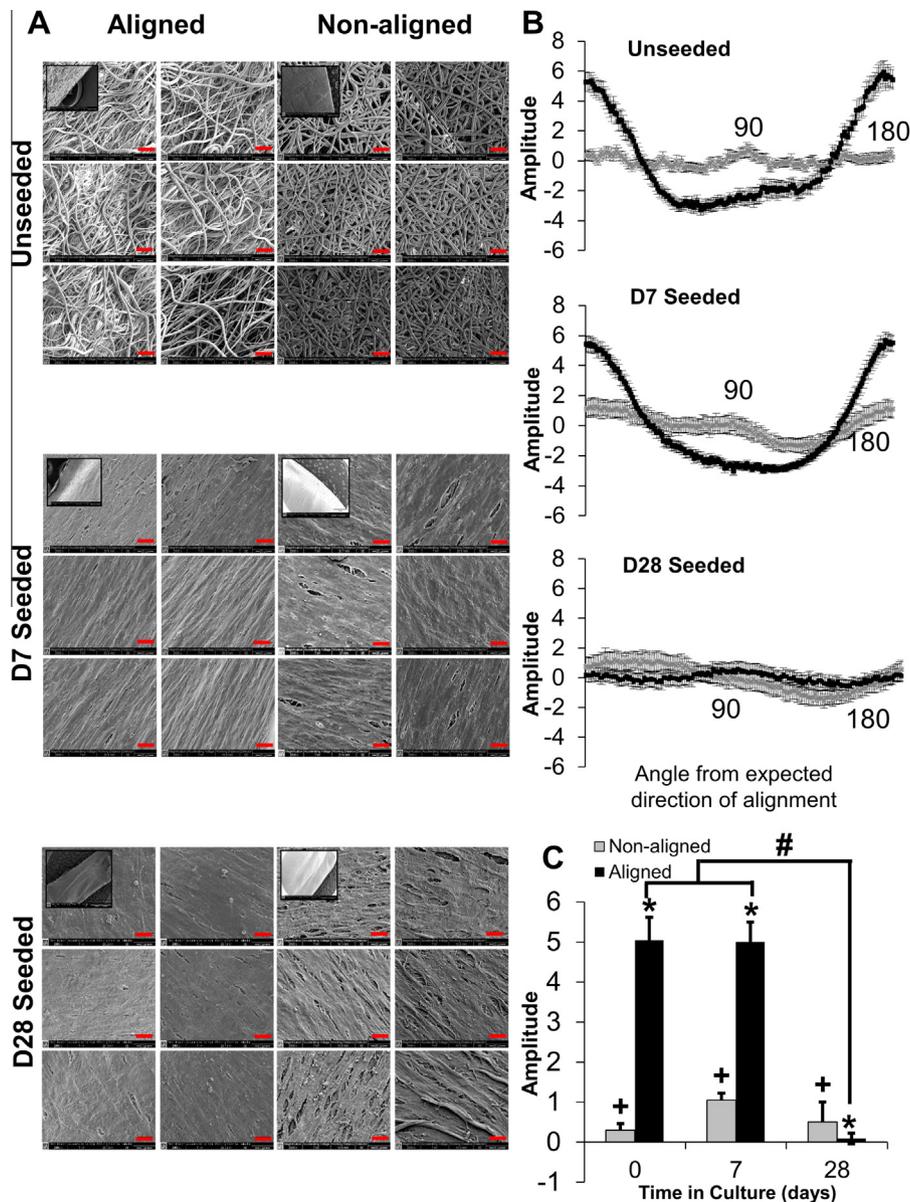

**Fig. 4.** Human type I and type III collagen immunofluorescence (fluorescein isothiocyanate; green) with nuclear counterstain (propidium iodide; red), and Picrosirius Red staining under visible and polarized light in aligned and nonaligned hASC-seeded scaffolds cultured for 28 days.

scaffolds, and similar collagen synthesis assessed by hydroxyproline assay, Picrosirius Red staining was enhanced on aligned compared to nonaligned scaffolds, and when evaluated by polarized light microscopy, red birefringence was present through the full thickness of the scaffolds in aligned but not nonaligned scaffolds. This finding indicates that the interior of aligned multilayered electrospun scaffolds supports development of both larger diameter and more aligned collagen fibrils compared to nonaligned multilayered scaffolds [60].

Examination of the surface alignment of the newly deposited ECM and cells demonstrated the expected alignment with aligned fiber orientation at 7 but not 28 days of culture. This finding is in contrast to another study in which cell alignment persisted on the surface of aligned scaffolds after 28 days [51]. However, initial cell seeding density in that study was 10-fold lower than the

current study, and cells were not confluent on the surface of the scaffolds after 28 days of culture. Emerging evidence suggests that response to microarchitectural cues, cell proliferation, migration, symmetry of cell–cell contacts, and direction of cellular and matrix alignment are tightly coordinated [61–65]. In the initial period after seeding on electrospun fibers, MSCs demonstrate potent directionality in their migration response and in their cell–cell contacts on aligned compared to nonaligned electrospun fibers [66]. In contrast, once cells are confluent on the surface of electrospun scaffolds and lose contact with fibers, cell–cell contact may become the predominant driver of direction of cellular alignment, unless mechanical stimulation is applied to the scaffolds to maintain alignment [51,67,68]. This loss of cell interaction with aligned fibers that occurs at the surface, leading to loss of overall cell alignment, does not occur in the three-dimensional fiber environment

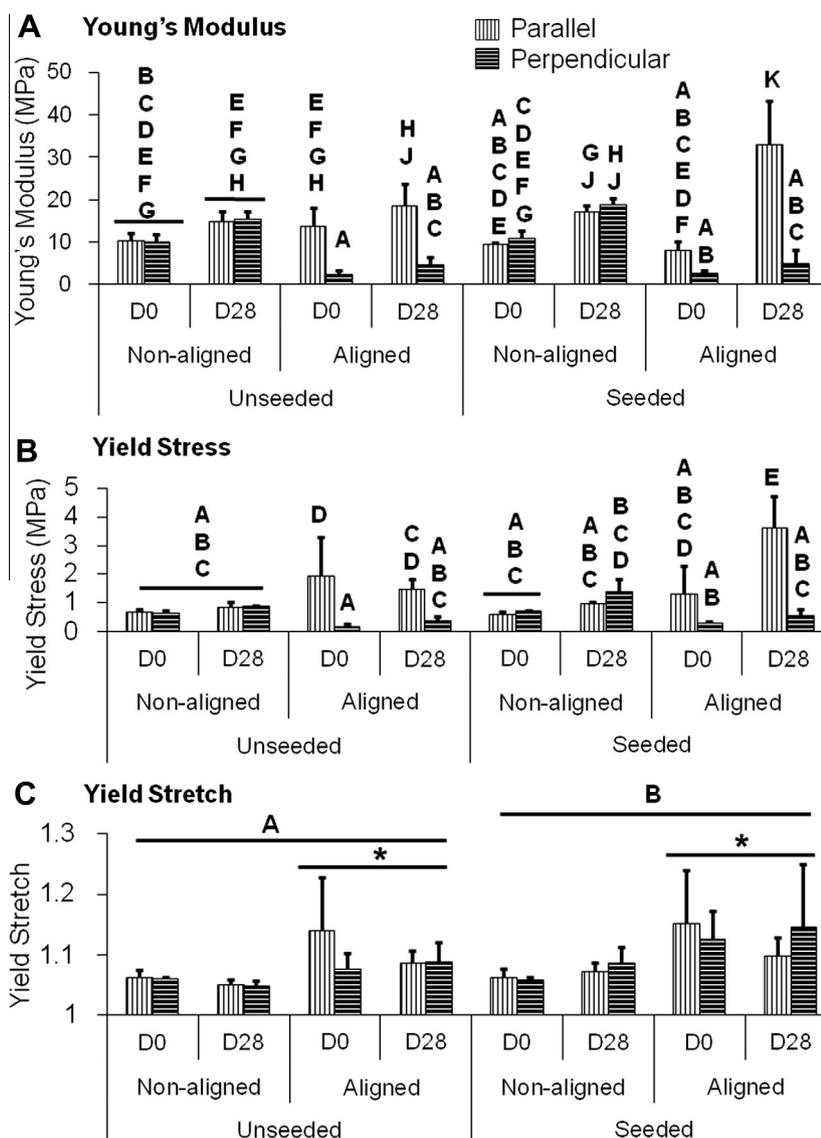

**Fig. 5.** Scanning electron micrographs of aligned and nonaligned scaffolds over 28 days in culture (A) Scale bar = 20  $\mu$ m. Inset images represent long axis scaffold border along direction of expected fiber alignment. Fast Fourier transform results (B) of the same scaffolds ( $n = 5, 6$  images/scaffold), and fiber alignment index (C) of aligned and nonaligned scaffolds. Plus symbol (+) indicates significantly different from other nonaligned bars with the same symbol, asterisk (\*) indicates different from nonaligned at same time point, and the hash sign (#) indicates day 0 and 7 different from day 28.

of the interior of the scaffold where cells continue to stimulate development of aligned collagen in aligned but not nonaligned scaffolds. In nonaligned multilayered scaffolds after seeding, surface cellular and matrix organization was not randomly oriented, since there were regions of local alignment within each nonaligned scaffold, similar to that reported previously (Fig. 5(A)) [36]. Interestingly, and in contrast to our previous study, there was a small but significant increase in fiber alignment index after 7 days on seeded nonaligned scaffolds compared to unseeded nonaligned scaffolds, in the direction of the long axis of the 0.5 cm  $\times$  1 cm cultured scaffold. This may be due to domination of macro-scale edge or boundary effects over the nano- and micro-scale architecture resulting in asymmetric cell–cell contacts and is the subject of current studies [61–63,65]. The surface alignment of cells and matrix on nonaligned scaffolds at day 7 was attenuated by 28 days, suggesting that boundary conditions may not be sufficient to maintain alignment on nonaligned scaffolds once cells become

super-confluent on the surface, and that mechanical load may be necessary to maintain and increase alignment [51].

The rapid synthesis of aligned fibrillar collagen in aligned scaffolds may account for the rapid increase in Young's modulus and yield stress of aligned hASC-seeded scaffolds after only 28 days in culture, and for the maintenance of anisotropy even in the absence of mechanical loading. The Young's modulus of these scaffolds after 28 days of culture is still only approximately 20–25% of that of the human supraspinatus tendon [69,70], but is of the same order of magnitude as many of the currently available ECM patches [71]. PCL, chosen for its neutral degradation profile and relatively slow degradation rate [72], has a relatively low tensile modulus when compared to many polymers commonly used in electrospinning for tissue engineering [73]. Continued evaluation of this technique using alternative polymers is likely to improve on these mechanical properties. One advantage of this multilayered alignment technique is that we can readily manipulate the alignment

**Fig. 6.** Mean Young's modulus (A), yield stress (B), and yield stretch (C) in seeded and unseeded aligned and nonaligned scaffolds tested in orthogonal dimensions after 0 and 28 days of culture. Whiskers indicate standard deviation;  $n = 6$ . Bars with different letters above are significantly different from each other,  $p \leq 0.05$ .

of individual layers within the vertical gradient and over different regions of the scaffold. This may ultimately reduce mismatch and stress concentration between the scaffold and the underlying supraspinatus tendon [74]. Additionally, since mechanical loading augments the effects of fiber alignment, further improvement in tensile mechanical properties are expected in bioreactor and *in vivo* studies.

**5. Conclusions**

In summary, the novel multilayered alignment technique described here produced anisotropic scaffolds up to 7.5 cm × 10 cm of a clinically relevant size and thickness that permitted early and complete cellular infiltration through the full thickness of the scaffold by hASCs, enhanced *TNMD* and *COL3A1* expression, alignment of newly synthesized fibrillar collagen, and early development of tensile mechanical properties compared to multilayered non-aligned scaffolds. With continued evaluation, this technique should lead to development of a new augmentation patch to improve on currently available treatment options for rotator cuff tear repair.
